Photothermal Intracellular Delivery Using Gold Nanodisk Arrays

Chuanzhen Zhao, Tianxing Man, Xiaobin Xu, Qing Yang, Wenfei Liu, Steven J. Jonas, Michael A. Teitell, Pei-Yu Chiou,* and Paul S. Weiss*

ABSTRACT: Local heating using pulsed-laser-induced photothermal effects on plasmonic nanostructured substrates can be used for intracellular delivery applications. However, the fabrication of plasmonic nanostructured interfaces is hampered by complex nanomanufacturing schemes. Here, we demonstrate the fabrication of large-area plasmonic gold (Au) nanodisk arrays that enable photothermal intracellular delivery of biomolecular cargo at high efficiency. The Au nanodisks (350 nm in diameter) were fabricated using chemical lift-off lithography (CLL). Nanosecond laser pulses were used to excite the plasmonic nanostructures, thereby generating transient pores at the outer membranes of targeted cells that enable the delivery of biomolecules via diffusion. Delivery efficiencies of >98% were achieved using the cell impermeable dye calcein (0.6 kDa) as a model payload, while maintaining cell viabilities at >98%. The highly efficient intracellular delivery approach demonstrated in this work will facilitate translational studies targeting molecular screening and drug testing that bridge laboratory and clinical investigations.

Intracellular delivery of exogenous cargo, such as nucleic acids,1–4 proteins,5,6 and membrane-impermeable drugs,6–8 is of great importance across a spectrum of biomedical and therapeutic applications, including precision gene modification,9–12 immunotherapy,13–15 intracellular imaging/sensing,16,17 drug delivery,6,8,18,19 and regenerative medicine.20,21 To date, efforts towards intracellular delivery have been advanced by carrier-based and membrane-disruption-based approaches.22–24 Viral-vector-based methods remain the most clinically advanced carrier-based strategies, achieving nucleic acid delivery with high efficiencies and specificities.25,26 However, challenges associated with their potential immunogenicity, safety concerns from off-target effects, complexity, and high costs have limited their broader application.27 Moreover, viral-based carrier systems suffer from intrinsic limitations in their cargo-carrying capacity, which preclude effective complex biomolecules or mixtures of components. Membrane-disruption-based approaches,23,27,28 where transient pores are created in cell membranes via mechanical,23,29–35 electrical,36,37 or photothermal methods,38–44 are less dependent on cargo and cell type.45 Electroporation-based methods yield appropriate efficiencies but suffer from low viability and require specialized equipment and reagents.22,46–49 Strategies using nanostructures, such as nanowires,50,51 nanostraws,52–54 and nanoneedles,55–58 to create pores in cell membranes, have also been shown to have suitable efficiencies and viabilities for intracellular delivery but are limited by poor reproducibility, slow processing throughputs, and complicated fabrication processes.

Photothermal strategies that utilize the generation of cavitation bubbles induced by laser irradiation of noble metal nanoparticles or metal plasmonic structures represent another promising membrane-disruption method.59,60 Upon laser irradiation, metallic nanostructures absorb incident photon energy through electron oscillations, which results in an abrupt temperature increase in the surrounding aqueous medium.61,62 Explosive cavitation bubbles nucleate when the temperature exceeds the critical temperature of the aqueous medium.63 Large fluid shear stress induced by the rapid expansion and collapse of cavitation generates transient and localized pores an adjacent cell membrane.64 The size of the cavitation bubbles depends on the laser fluences radiated, which has been previously studied to be in the range of 100 nm to 1 μm.64 Previous studies have demonstrated that noble metal nanoparticles, such as Au nanoparticles, are well suited to serve as high-efficiency delivery agents.18–44,65,66 However, the cytotoxicity of Au nanoparticles is still under investigation, and this method also suffers from limitations in reproducibility. For
Figure 1. Illustration of photothermal intracellular delivery enabled by localized surface plasmon resonance (LSPR) of gold nanodisks excited by a nanosecond laser. After cell seeding, the laser was rastered over cells seeded onto the nanostructures and cultured in a medium containing membrane impermeable biomolecules. Upon irradiation, the gold plasmonic structures heat up rapidly and generate cavitation bubbles, which facilitate the delivery of the biomolecular cargo into targeted cells by creating transient pores along nearby their outer membranes.

example, it has been shown that the number and the location of pores created on each cell is not well controlled due to the random distribution of nanoparticles. Moreover, high delivery efficiencies achieved with increased nanoparticle concentration typically resulted in compromised cell viability.67 Alternatively, substrate-supported plasmonic structures, fabricated using micro- and nanolithography techniques, serve as promising platforms for high-efficiency and high-viability intracellular delivery.6,8,19,68 In addition, because of the physical separation of the nanostructures, the stoichiometry of the interactions with the cells can be controlled precisely (as compared to the case for plasmonic nanoparticles). Current methods of producing plasmonic architectures for photothermal delivery applications are limited by time consuming and costly conventional nanolithographic fabrication processes (e.g., electron-beam lithography) used to pattern metal layers, which hinder the scalability of these techniques and represent a critical barrier to applying these technologies to clinical targets. Alternatively, nanofabrication approaches that yield repeatable, scalable, and economical production of plasmonic nanostructures could facilitate consideration of this approach for wide-scale clinical applications. Recent advances have been made in producing plasmonic structures using template-stripping processes. For example, nanoporous structures have been fabricated in an economical and high-throughput manner.8 However, challenges remain for a facile fabrication process as the template stripping process requires the fabrication on a polymer layer and an extra transfer process.

Soft lithography uses soft polymeric stamps to fabricate a range of micro- and nanoscale features in a high-throughput, large-scale, and cost-effective manner.69,70 Microcontact printing (μCP), as a representative soft lithography method, transfers molecular inks, such as alkanethiols, from stamp to target surfaces.70,71 A complementary, subtractive soft lithography process chemical lift-off lithography (CLL), uses oxygen plasma-activated polydimethylsiloxane (PDMS) stamps to remove self-assembled monolayer (SAM) molecules selectively from contacted areas on surfaces to create patterns over large areas, and may be used to achieve high-fidelity chemical patterns with line widths approaching 5 nm (corresponding to patterns ~10 nm molecules across).72–75 The remaining SAM molecules in the non-lift-off regions can act as resists to enable selective etching of exposed Au to produce Au nanostructures, such as Au nanolines, nanocircles, and nanosquares.74,79–81

In this work, we apply CLL to achieve fabrication of Au plasmonic nanostructures over large areas for photothermal intracellular delivery. Large-area two-dimensional (2D) Au nanodisk arrays are fabricated across centimeter length scales on a variety of substrates, such as silicon wafers, glass slices, and plastic petri dishes, which provides a significant advantage for versatile intracellular delivery environments and creates opportunities for integration with medical devices. Nanodisk arrays of different sizes have been fabricated in this study to measure delivery efficiencies and cell viabilities as a function of nanostructure surface density per cell. Upon excitation of the nanodisks with a nanosecond laser, delivery efficiencies of >98% and cell viabilities of >98% were achieved using 0.6 kDa cell membrane-impermeable calcein as a model cargo molecule, which is comparable with current photothermal intracellular delivery platforms. This work demonstrates a promising economical and reproducible intracellular delivery approach, with widespread applicability for drug delivery, nanoparticle delivery, and regenerative medicine.

We exploit the plasmonic properties of the gold nanodisks, whereby exposure to nanosecond laser pulses generates cavitation bubbles with energies sufficient to puncture cellular membranes, forming pores that facilitate intracellular delivery of desired cargo (Figure 1). HeLa cells, used as a model cell line, were cultured onto CLL-patterned nanodisk substrates and placed in a growth medium containing calcein. By scanning the laser across the wafer-scale Au plasmonic substrate, plasmonic hotspots formed upon illumination. Cavitation bubbles generated at these local regions in contacting the plasma membranes of the target HeLa cells serve as projectiles that render the cells transiently permeable. Cargo molecules within the surrounding medium are able to enter the cytoplasm via diffusion.6 Precision control of the pulsed-laser spot position across the substrate is maintained with a pair of X–Y scanning mirrors. It takes 10 s to scan across the entire 25 mm2 chip, with over 104 cells per chip.

The fabrication of periodic metal nanostructures with micron-scale features can be achieved readily via conventional photolithography, while producing sub-micron features often requires specialized tools, such as electron beam lithography (EBL) and focused ion beam lithography (FIB). However, these serial writing processes systems are time consuming and costly to operate, leading to extremely limited production yields and output. Transfer printing techniques, such as nanotransfer printing, provide an alternative solution for nanofabrication over large areas while achieving higher processing throughputs.77 Existing nanoscale printing approaches are limited to certain substrates based on surface energy constraints that are critical for successful and reproducible pattern transfer. In this study, we extend the applications of CLL for biomedical applications. Double-patterning CLL has been recently reported as a means of fabricating Au plasmonic nanodisk arrays (Figure 2a).81
Polydimethylsiloxane stamps, textured with lines of different widths and pitches, are activated by exposure to oxygen plasma to generate hydrophilic silanol groups on their surfaces. Substrates for CLL (e.g., silicon wafers) are coated with a thin layer of Au (30 nm) that is functionalized with a hydroxyl-terminated alkanethiol (11-mercapto-1-undecanol) SAM. Conformal contact between the stamp and the substrate leads to condensation reactions between OH-groups of SAM and the silanol groups of activated PDMS, leading to the formation of covalent bonds (Si−O−SAM). Lifting the stamp from the substrate results in selective removal of the SAM corresponding to the stamp’s pattern, leaving SAM molecules within the non-contacted regions that establish a series of nanoscale lines. A second CLL step was then performed by rotating the stamp 90° to generate two-dimensional (2D) nanosquare chemical patterns. Exposed metal was removed via wet etching to generate Au 2D nanodisk arrays. A representative image of a Au nanodisk array on a petri dish is shown in Figure 2b, where the central area contains uniformly patterned plasmonic nanostructures over centimeters scales. We extend the capabilities of this technique by demonstrating fabrication on multiple materials (e.g., plastic petri dishes) that are easily coated with Au thin films and then modified via CLL patterning (Figure 2c). The ease of integration with commercially available cell culture products demonstrates the potential of our platform to add new functionality to existing medical devices, enabling opportunities for controlled in situ drug delivery and molecular screening. Stamps with periodic lines of different feature sizes were used in this study, with widths ranging from 350 nm to 10 μm and pitches ranging from 700 nm to 20 μm. To create submicron features, we used commercial optical storage products, such as DVDs (~$1 each), as masters that contain large-area, periodic gratings with 350 nm wide at 700 nm pitch to circumvent the need for expensive and slow lithographic techniques, such as EBL. Atomic force microscope (AFM)
images show the morphology of the fabricated Au nanodisks, with widths of 350 nm (Figure 2d), 1 μm (Figure 2e), and 2 μm (Figure 2f). The nanostructures maintain uniform shape with sharp edges, as seen in the AFM images. Corresponding optical microscope images that demonstrate the capability to tune the microscale widths of the patterned structures at 350 nm (Figure S1), 1 μm (Figure 2g), 2 μm (Figure 2h), and 10 μm (Figure 2i).

Plasmonic nanodisk arrays fabricated in this manner are promising candidates for substrates for surface plasmonic resonance (SPR) measurements. Surface plasmon resonance properties of Au nanodisks are studied in separate work. Therefore, we hypothesized that these plasmonic structures could be applied for photothermal delivery, where sharp edges concentrate effectively laser energy to generate cavitation bubbles in the cell culture medium. Explosive boiling of water will occur when the temperature reaches 80−90% of its critical temperature (∼650 K) that enables the bubbles formed in close proximity to a cell to puncture its outer membrane discretely. Finite element analysis simulations (COMSOL, Multiphysics 4.4) were conducted that estimate that the aqueous cell culture medium reaches above 640 K (∼360 °C) locally at laser irradiances of 11 mJ/cm² (Figure 3h, i), which is sufficient to initiate cavitation bubble formation. We have performed the simulations on different dimensions of Au nanodisk arrays, which show temperature increases between 636 and 644 K upon laser radiation across different nanodisk array sizes (Figure S2). Calcein AM (AM = acetoxymethyl), a cell membrane permeable variant of calcein, was used for short-term labeling of HeLa cells, as shown in Figure 3a, prior to fixation on a 1-μm wide nanodisk array. An overlay of the optical and SEM images, within the green box (Figure 3b), is presented in Figure 3c with matching cell distribution and morphology. Results of fluorescence image of calcein, cell fixation, and an image overlay on 2-μm wide nanodisk arrays are shown in Figure 3d−f, respectively. Single cell morphology on a 2-μm wide nanodisk array was shown in Figure 3g with diameters of ∼20 μm.

We next demonstrated delivery of calcein green (0.6 kDa membrane impermeable cargo) with high efficiency and high viability. A schematic of optical setup is shown in Figure S3.
Calcein delivery using Au nanodisks (1 μm radius, 2 μm pitch, 30 nm thick) under 11 mJ/cm² laser irradiation can be seen in Figure 4a. Hoechst 33342, a cell-permeable nucleus fluorescence dye that emits at 497 nm, was used to label cell nuclei to quantify the total number of cells (Figure 4b). Propidium iodide (PI), which is not permeable to live cells, was used to detect dead cells (Figure 4c). Overlaid images of calcein green fluorescence, Hoechst 33342 nucleus staining, and PI staining were taken 90 min after laser pulsing and are shown in Figure 4d. Efficiency was determined to be 98 ± 1%, with a viability of 99 ± 1% under the condition described above, with three independent experiments of ~740 cells in total. Control experiments were performed on uniformly flat gold films (30 nm thick) under the same conditions show negligible delivery efficiency, which verifies the critical role of the Au nanostructure in the intracellular delivery of calcein green under laser irradiation. It has been shown previously for similar systems that the cells will have minimal Au residue after laser radiation.

Different laser fluences, ranging from 7 to 21 mJ/cm², were studied to optimize delivery performance (Figure 5a, b). We observed that the number of cells receiving the calcein cargo (green) decreased while cytotoxicity (red) increased with increasing laser fluence. Additional experiments studying the effect of different laser fluences were performed with results plotted in Figure 5e. Over 2500 cells were counted for each sample tested. Delivery efficiencies increased when the laser fluence was increased from the minimum laser intensity up to 11 mJ/cm², reaching 98 ± 1% efficiency. At higher laser fluences, both cell viability and efficiency decreased significantly (with viability decreasing to 16 ± 2% and 6 ± 1% efficiency at 21 mJ/cm²). We attribute this cytotoxicity to irreversible membrane disruption occurring at the higher laser intensities. The delivery efficiency decrease with cell viability is expected, as calcein will only remain in live cells.

We also studied the effects of width and pitch of the periodic nanodisk arrays on delivery performance. Fewer calcein-delivered cells were observed as the sizes of Au nanodisks were increased from 2 to 10 μm (Figure 5c, d), while the numbers of dead cells (red) remained the same relative to the total number of cells (blue). This phenomenon can be explained by the density of cavitation bubbles induced by the gold plasmonic structures per cell. Results from our
simulations of photothermal response (Figure 3f) indicate that hotspots occur at the corner of each nanodisk where the pitch of nanodisk array is twice the width of an individual disk. Disk arrays with larger disk widths have fewer hotspots and thus form fewer cavitation bubbles. Delivery efficiency, therefore, decreases on these substrates because of the smaller numbers of cavitation bubbles. Our data indicate that the delivery efficiency is maximized for disks with widths smaller than 2 μm. Delivery efficiency and cell viability results on nanodisk arrays with different feature widths are shown in Figure 5f. Cargos with different sizes were also studied, including 0.6 kDa calcein, 4 kDa calcein, and a 150 kDa dextran (Figure 5g). Delivery efficiencies of 98 ± 1% and 94 ± 1% were achieved for 0.6 and 4 kDa calcein, respectively. Decreased efficiency of 36 ± 5% was observed for the dextran, which we infer is related to its lower diffusion coefficient. Note that the gold nanodisk substrates have the added benefit of being reusable, as we did not observe any drop in performance after five experiments (Figure S4).

In summary, effective and safe delivery of biomolecular cargos intracellularly was achieved by exposing large-area gold plasmonic substrates fabricated using double-patterning CLL to nanosecond-laser pulses. Gold surfaces patterned with 2D SAM nanosquare arrays were used to create sub-micron nanostructures. Illuminating the gold nanostructures with nanosecond laser pulses induced cavitation bubbles at the plasmonic hotspots through a photothermal effect. Cells seeded on the nanostructures were rendered transiently porous upon contact with the bubbles, enabling delivery of exogenous biomolecular cargo. Laser fluences and nanodisk sizes were optimized to achieve delivery efficiencies of over 98% for 0.6 kDa calcein with cell viability maintained at over 98%. Note that we attribute the photothermal delivery predominantly to the shear force generated by the formation and collapse of the cavitation bubble, but we do not exclude the effects of local thermal heating of the plasma membrane.

Desirable features of this CLL-based strategy include: (1) cost-effective and high-throughput fabrication of uniform nanostructures over large (square centimeter) areas, (2) versatile substrate selection, (3) scalability and reproducibility, and (4) economical setup that does not require specialized instrumentation. Efficient delivery of membrane impermeant small molecules to HeLa cells with minimal cell death was achieved, which opens new opportunities for testing and manipulating in disease-relevant cellular targets and potential integration with medical devices. Both the PDMS stamps and the fabricated plasmonic substrates are reusable, enabling scale-up to larger formats. Compared with femtosecond lasers sometimes used in laboratory studies, the nanosecond pulsed laser used here is economical and straightforward to operate. This study demonstrates a promising method for high-efficiency intracellular delivery for cellular therapeutic and drug-discovery applications. In this work, we focused on delivery of small molecules into HeLa cells. Previously, we have shown that our photothermal delivery platform can be applied to deliver large functional cargos, such as live bacteria, proteins, and plasmids, into a variety of cell types, including primary normal human dermal fibroblasts and human B lymphocyte cells. Further optimization and investigations of the Au nanodisk arrays will focus on advancing this technique so as to enable clinical applications, such as gene therapy and cancer immunotherapy.
